Hydrostatic pressure exerted on synaptosomes can markedly affect the uptake of calcium ions. The rates of calcium uptake under control conditions are inversely related to the free calcium concentration in the external medium. The permeability to calcium is directly related to the total calcium concentration in the medium, even when both the extracellular and the intracellular free calcium concentrations are in the micromolar range. Calcium uptake is always increased when synaptosomes are submitted to a hydrostatic pressure greater than 10(5) dyn/cm2. This phenomenon does not appear to be related to a cation diffusion. On the other hand, the reduction of the cytosolic free calcium concentration caused by the addition of a calcium-binding protein, calmodulin, at physiological concentrations, or by the incorporation of calcium in a highly permeable complex, such as casein, is drastically increased by hydrostatic pressure. The effect of calcium-binding proteins on calcium transport appears to be reversed by the hydrostatic pressure, thus supporting the presence of a calcium-dependent protein kinase in the inner synaptosomal membrane.
